

Mapping radii of metric spaces*

George M. Bergman

March 2, 2014

Abstract

It is known that every closed curve of length ≤ 4 in \mathbb{R}^n ($n > 0$) can be surrounded by a sphere of radius 1, and that this is the best bound. Letting S denote the circle of circumference 4, with the arc-length metric, we here express this fact by saying that the *mapping radius* of S in \mathbb{R}^n is 1.

Tools are developed for estimating the mapping radius of a metric space X in a metric space Y . In particular, it is shown that for X a bounded metric space, the supremum of the mapping radii of X in all convex subsets of normed metric spaces is equal to the infimum of the sup norms of all convex linear combinations of the functions $d(x, -) : X \rightarrow \mathbb{R}$ ($x \in X$).

Several explicit mapping radii are calculated, and open questions noted.

1 The definition, and three examples.

Definition 1. We will denote by **Metr** the category whose objects are metric spaces, and whose morphisms are nonexpansive maps. That is, for metric spaces X and Y we let

$$(1) \quad \mathbf{Metr}(X, Y) = \{f : X \rightarrow Y \mid (\forall x_0, x_1 \in X) \ d(f(x_0), f(x_1)) \leq d(x_0, x_1)\}.$$

Throughout this note, a map of metric spaces will mean a morphism in **Metr**.

Given a nonempty subset A of a metric space Y , we define its radius by

$$(2) \quad \text{rad}_Y(A) = \inf_{y \in Y} \sup_{a \in A} d(a, y),$$

a nonnegative real number or $+\infty$. For metric spaces X and Y , we define the mapping radius of X in Y by

$$(3) \quad \begin{aligned} \text{map-rad}(X, Y) &= \sup_{f \in \mathbf{Metr}(X, Y)} \text{rad}_Y(f(X)) \\ &= \sup_{f \in \mathbf{Metr}(X, Y)} \inf_{y \in Y} \sup_{x \in X} d(f(x), y). \end{aligned}$$

If X is a metric space and \mathbf{Y} a class of metric spaces, we likewise define

$$(4) \quad \begin{aligned} \text{map-rad}(X, \mathbf{Y}) &= \sup_{Y \in \mathbf{Y}} \text{map-rad}(X, Y) \\ &= \sup_{Y \in \mathbf{Y}, f \in \mathbf{Metr}(X, Y)} \inf_{y \in Y} \sup_{x \in X} d(f(x), y). \end{aligned}$$

(Note: the term “mapping radius” occurs occasionally in complex analysis with an unrelated meaning [12, Def. 7.11].)

All vector spaces in this note will be over the field of real numbers.

The result stated in the first sentence of the abstract has been discovered many times [3], [4], [15], [16], [22]. (Usually, the length of the closed curve is given as 1 and the radius of the sphere as $1/4$, but the scaled-up version will be more convenient here.) Let us obtain it in somewhat greater generality.

*2000 Mathematics Subject Classifications. Primary: 54E40. Secondary: 46B20, 46E15, 52A40.

Keywords: nonexpansive map between metric spaces, maximum radius of image, convex subset of a normed linear vector space.

This preprint is readable online at <http://math.berkeley.edu/~gbergman/papers/>.

Lemma 2. *Let S denote the circle of circumference 4, with the arc-length metric. Then for any nonzero normed vector space V , we have $\text{map-rad}(S, V) = 1$.*

Proof. In V , any 1-dimensional subspace is isometric to the real line \mathbb{R} , and we can map S into \mathbb{R} by “folding it flat”, getting for image an interval of length 2. This has radius 1 in V , so $\text{map-rad}(S, V) \geq 1$.

For the reverse inequality, consider any map $f : S \rightarrow V$. We wish to find a point $y \in V$ having distance ≤ 1 from every point of $f(S)$. Let p and q be any two antipodal points of S , and $y = (f(p) + f(q))/2$. Every point $x \in S$ lies on a length-2 arc between p and q in S , hence $d(p, x) + d(q, x) = 2$, hence $d(f(p), f(x)) + d(f(q), f(x)) \leq 2$, i.e., $(d(f(p), f(x)) + d(f(q), f(x)))/2 \leq 1$, so $d((f(p) + f(q))/2, f(x)) \leq 1$, as claimed. \square

Let us make explicit the argument used at the very last step above. It is the $c_1 = c_2 = 1/2$ case of

- (5) If c_1, \dots, c_n are nonnegative real numbers summing to 1, and v_1, \dots, v_n are elements of a normed vector space V , then for all $w \in V$, $d(\sum c_i v_i, w) \leq \sum c_i d(v_i, w)$.

This can be seen by writing the left-hand side as $\|(\sum c_i v_i) - w\| = \|\sum c_i (v_i - w)\| \leq \sum \|c_i (v_i - w)\| = \sum c_i d(v_i, w)$.

Consider next the union X of two circles S_0 and S_1 , each of circumference 4, intersecting in a pair of points antipodal in each (e.g., take for S_0 and S_1 any two distinct great circles on a sphere of circumference 4), again with the arc-length metric. We can show that this X also has mapping radius ≤ 1 in V by the same argument as before, except that where we previously used an arbitrary pair of antipodal points, we are now forced to use precisely the pair at which our circles intersect. We are not so restricted in the example showing that radius 1 can actually be achieved – we can stretch one circle taut between any two antipodal points, and for most choices of those points, we have a great deal of freedom as to what to do with the other circle. In any case, we have

Lemma 3. *Let X be the union of two circles S_0 and S_1 , each of circumference 4, intersecting in a pair of points antipodal in each, with the arc-length metric. Then for any nonzero normed vector space V , we have $\text{map-rad}(X, V) = 1$.* \square

We could apply the same method to any number of circles joined at a common pair of antipodal points; but let us move in a different direction. Again picturing S_0 and S_1 as great circles on a sphere of circumference 4 in Euclidean 3-space, assume they meet at right angles, and call their points of intersection the north and south poles. Let us bring in a third circle, S_2 , the equator, and let $X = S_0 \cup S_1 \cup S_2$, again with the arc length metric.

We no longer have a pair of antipodal points belonging to all three circles; rather, we have three pairs of points, $S_1 \cap S_2 = \{p_0, q_0\}$, $S_2 \cap S_0 = \{p_1, q_1\}$, and $S_0 \cap S_1 = \{p_2, q_2\}$. Now given a normed vector space V and a map $f : X \rightarrow V$ in **Metr**, suppose we let

$$(6) \quad y = (f(p_0) + f(q_0) + f(p_1) + f(q_1) + f(p_2) + f(q_2))/6.$$

What can we conclude about $d(y, f(x))$ for $x \in X$?

Say $x \in S_2$. Since both $\{p_0, q_0\}$, and $\{p_1, q_1\}$ are pairs of antipodal points of S_2 , we have $d(p_0, x) + d(q_0, x) = d(p_1, x) + d(q_1, x) = 2$. The same will not be true of $d(p_2, x)$ and $d(q_2, x)$. To determine how large these can get, let us take $x \in S_2$ as far as possible from the intersections of S_2 with our two circles through the poles p_2 and q_2 . This happens when x is at the midpoint of any of the quadrants into which p_0, q_0, p_1 and q_1 divide S_2 ; in this situation, $d(p_2, x) = d(q_2, x) = 3/2$. (Each quadrant has arc-length 1, and one has to go a quadrant and a half to get from p_2 or q_2 to x .) We see, in fact, that for any $x \in S_2$ we have $d(p_2, x) = d(q_2, x) \leq 3/2$, hence $d(p_2, x) + d(q_2, x) \leq 3$. Now applying any map $f : X \rightarrow V$, and invoking (5) with all $c_i = 1/6$, we see that for y as in (6) we have $d(y, f(x)) \leq (2 + 2 + 3)/6 = 7/6$. We have proved this for $x \in S_2$; by symmetry, it is also true for x lying on S_0 or S_1 . This allows us to conclude, not that $\text{map-rad}(X, V) = 1$ as in the preceding two cases, but that

$$(7) \quad \text{map-rad}(X, V) \leq 7/6.$$

And in fact, there do exist maps $f : X \rightarrow V$ with $\text{rad}_V(f(X)) > 1$. To describe such a map, note that X can be identified with the 1-skeleton of an octahedron of edge 1. In the next few paragraphs, let us put aside our picture of X in terms of great circles on a sphere, and replace it with this (straight-edged) octahedral skeleton.

If we look at our octahedron in Euclidean 3-space from a direction perpendicular to one of its faces, we see that face and the opposite one as overlapping, oppositely oriented equilateral triangles, with vertices joined by the projections of the remaining 6 edges, which form a regular hexagon. Now suppose we regard these two opposite triangular faces as made of stiff wire, and the other 6 edges as made of string. Then if we bring the planes of the two wire triangles closer to one another, the string edges will loosen. Suppose, however, that we rotate the top triangle clockwise as they approach one another, so that three of these edges are kept taut, while the other three become still looser. When the planes of our wire triangles meet, those wire triangles will coincide, and the three taut string edges will fall together with the three edges of that triangle, while the three loose ones become loops, hanging from the three vertices. Let us lock the two wire triangles together, and pull the three loops taut, radially away from the center of symmetry of the triangle.

What we then have is the image of a certain map f in **Metr** from our octahedral skeleton X into a plane, which we can identify with \mathbb{R}^2 . We see that $\text{rad}_{\mathbb{R}^2}(f(X))$ will be the distance from the center of symmetry of our figure to each of the three points to which the drawn-out loops are stretched; i.e., the sum of the distance from the center of symmetry to each vertex of the triangle, and the length of the stretched loop attached thereto. The former distance is two thirds of the altitude of the triangle, or $(2/3)(\sqrt{3}/2) = 1/\sqrt{3}$, and the latter length is $1/2$ (since the loop doubles back), so

$$(8) \quad \text{rad}_{\mathbb{R}^2}(f(X)) = 1/\sqrt{3} + 1/2. \quad \text{Hence, } \text{map-rad}(X, \mathbb{R}^2) \geq 1/\sqrt{3} + 1/2 > 1.$$

This shows that our three-circle space does indeed behave differently from the preceding one- and two-circle examples.

However $1/\sqrt{3} + 1/2 \approx 1.0773$, which falls well short of the upper bound $7/6 \approx 1.1667$ of (7).

We can overcome this deficiency by using a different norm on \mathbb{R}^2 . Let V be \mathbb{R}^2 with the norm whose unit disc is the region enclosed by a regular hexagon H of unit side. Note that the 6 sides of H are parallel to the 6 radii from 0 to the vertices of H , hence these sides have length 1 in the new metric, just as in the Euclidean metric; hence any line segment in one of those directions will have the same length in both metrics. Now let us map X , still pictured as the 1-skeleton of a regular octahedron of side 1 in Euclidean 3-space, into V so that, as before, two opposite triangles are embedded isometrically (now under the metric of V), and made to fall together with each other and with three of the other edges, while the remaining three edges form loops that are stretched radially outward as far as they will go. Let us moreover take the sides of our image-triangle to be parallel to three sides of H .

The map $X \rightarrow \mathbb{R}^2$ that does this is almost the same one as before. The 9 edges that end up parallel to edges of H are mapped exactly as before, since distances in those directions are the same in the two metrics. The three folded loops end up set-theoretically smaller than before, since the new metric is greater in their direction than is the Euclidean metric, and they go out a distance $1/2$ in the *new* metric before turning back; but they still contribute the value $1/2$ to the calculation of the radius of our image of X . The significant change is in the distance from the center of our triangle to its three vertices. Looking at our triangle as a translate of one of the 6 equilateral triangles into which H is decomposed by radii from its center, we see that its altitude is equal to its side in this metric (since the midpoint of a side of H has the same distance, 1, from the origin as a vertex of H does). Hence the distance from the center to a vertex is $2/3$. Adding to this the distance $1/2$ from that vertex to the end of the loop attached to it, we get $2/3 + 1/2 = 7/6$. Assuming that the center of our triangle is indeed the minimizing point defining the radius (i.e., is a value of y that yields the infimum (2); we will verify this in Lemma 5), this achieves the upper bound (7). Summarizing, and making a few supplementary observations, we have

Lemma 4. *Let X be the 1-skeleton of a regular octahedron of side 1, under the arc-length metric. Then for any nonzero normed vector space V ,*

$$(9) \quad 1 \leq \text{map-rad}(X, V) \leq 7/6.$$

The exact value of $\text{map-rad}(X, V)$ is 1 if V is 1-dimensional, is $\geq 1/\sqrt{3} + 1/2$ if V is \mathbb{R}^n ($n \geq 2$) under the Euclidean norm, and is $7/6$ if V is \mathbb{R}^2 under the norm having for unit circle a regular hexagon.

Proof. The lower bound 1 in (9) is gotten as in the last full sentence before Lemma 3, by regarding X as $S_0 \cup S_1 \cup S_2$, straightening out one of these circles to cover a segment of length 2 in a 1-dimensional subspace of V , and letting the other two circles collapse into that line in any way. (Or for a construction that relies less on geometric intuition, pick any $p \in S_0$, map X into \mathbb{R} by the function $d(p, -)$, note that this map sends p and the point antipodal to p on S_0 to 0 and 2, respectively, and embed \mathbb{R} in V .) Since such an image of X has points 2 units apart, it has radius ≥ 1 in V by the triangle inequality. The upper bound $7/6$ was obtained in (7).

To show that when V itself is 1-dimensional, the value 1 is not exceeded, one verifies that the distance between any two points of X is ≤ 2 , hence the image of X under any map into such a V is a segment of length ≤ 2 , hence of radius ≤ 1 .

The lower bounds $1/\sqrt{3} + 1/2$ and $7/6$ for $V = \mathbb{R}^2$ with the two indicated norms were obtained above by explicit mappings. \square

Let us now justify the assumption we made just before the statement of the above lemma, about the center from which we computed the radius.

Lemma 5. *Let V be a normed vector space, A a nonempty subset of V , and G a finite group of isometries of V which preserve A . Then*

$$(10) \quad \text{rad}_V(A) = \inf_{y \in V^G} \sup_{a \in A} d(a, y),$$

where V^G is the fixed-point set of G .

In particular, if V^G is a singleton $\{v_0\}$, then

$$(11) \quad \text{rad}_V(A) = \sup_{a \in A} d(a, v_0).$$

Proof. Given $v \in V$, let

$$(12) \quad y = |G|^{-1} \sum_{g \in G} gv,$$

and note that this point lies in V^G , and that for any $a \in A$,

$$(13) \quad \begin{aligned} d(y, a) &= d(|G|^{-1} \sum_{g \in G} gv, a) \leq \sum_{g \in G} |G|^{-1} d(gv, a) = |G|^{-1} \sum_{g \in G} d(v, g^{-1}a) \\ &\leq |G|^{-1} \sum_{g \in G} \sup_{b \in A} d(v, b) = \sup_{b \in A} d(v, b). \end{aligned}$$

Here the first inequality holds by (5) and the second by considering $b = g^{-1}a$. Hence for $y \in V^G$ defined by (12), $\sup_{a \in A} d(y, a) \leq \sup_{a \in A} d(v, a)$, from which (10) follows. The final assertion is a special case. \square

For $V = \mathbb{R}^2$ with a regular hexagon as unit circle, the group G generated by a rotation by $2\pi/3$ about any point is an isometry of V , and if we take that point to be the center of symmetry of the set $f(X)$ we were looking at above, G preserves $f(X)$ and has that center of symmetry as unique fixed point; so the above lemma justifies our description of the radius of $f(X)$ in terms of distance from that point. In the corresponding computation for the Euclidean metric on \mathbb{R}^2 , we “saw” that the radius was measured from the center of symmetry; this is likewise justified by Lemma 5.

Lemma 4 leaves open

Question 6. *For $V = \mathbb{R}^2$ under the Euclidean norm, and X the 1-skeleton of a regular octahedron of side 1, where does $\text{map-rad}(X, V)$ lie within $[1/\sqrt{3} + 1/2, 7/6]$?*

For $V = \mathbb{R}^n$, again with the Euclidean norm, but $n > 2$, is the answer the same?

Having whetted our appetite with this example, let us now prove some general results.

2 General properties of mapping radii.

Lemma 7. *Let X, X', Y, Y' be nonempty metric spaces, \mathbf{Y} and \mathbf{Y}' classes of such metric spaces, and V and V' normed vector spaces.*

(i) *If there exists a surjective map $h : X \rightarrow X'$ (or more generally, a map $X \rightarrow X'$ with dense image) in*

Metr, then $\text{map-rad}(X', Y) \leq \text{map-rad}(X, Y)$.

(ii) If $Y' \subseteq Y$, then for any nonempty subset A of Y' we have $\text{rad}_{Y'}(A) \geq \text{rad}_Y(A)$. Here equality will hold if Y' is a retract of Y ; i.e., if the inclusion of Y' in Y has a left inverse in **Metr**.

Hence if Y' is a retract of Y , then $\text{map-rad}(X, Y') \leq \text{map-rad}(X, Y)$. In particular, this is true if Y is a normed vector space (or more generally, a convex subset of such a space) and Y' the fixed subspace of a finite group G of affine isometries of Y .

(iii) If $\mathbf{Y}' \subseteq \mathbf{Y}$, then $\text{map-rad}(X, \mathbf{Y}') \leq \text{map-rad}(X, \mathbf{Y})$.

(iv) In contrast to (i) and (ii), for $X' \subseteq X$, either of the numbers $\text{map-rad}(X', Y)$ and $\text{map-rad}(X, Y)$ can be greater than the other, and if $Y' \subseteq Y$, or if Y' is a surjective image of Y in **Metr**, either of the numbers $\text{map-rad}(X, Y')$ and $\text{map-rad}(X, Y)$ can be greater than the other.

Proof. (i) Suppose $h : X \rightarrow X'$ has dense image. Then for any $f : X' \rightarrow Y$, $fh(X)$ is dense in $f(X')$, hence $\text{rad}_Y(fh(X)) = \text{rad}_Y(f(X'))$, so the terms of the supremum defining $\text{map-rad}(X, Y)$ include all the terms of the supremum defining $\text{map-rad}(X', Y)$, from which the asserted inequality follows.

(ii) The terms of the infimum defining $\text{rad}_Y(A)$ include the terms of the infimum defining $\text{rad}_{Y'}(A)$, giving the first inequality.

If there exists a retraction e of Y onto Y' , then for every $y \in Y$ and $a \in A$ we have $d(e(y), a) \leq d(y, a)$, since e is nonexpansive and fixes points of A . Hence $\sup_{a \in A} d(e(y), a) \leq \sup_{a \in A} d(y, a)$, and taking the infimum of this over $y \in Y$, we get $\text{rad}_{Y'}(A) \leq \text{rad}_Y(A)$. This and the previous inequality give the asserted equality. Since $\mathbf{Metr}(X, Y') \subseteq \mathbf{Metr}(X, Y)$, we also get $\text{map-rad}(X, Y') \leq \text{map-rad}(X, Y)$, as claimed.

If Y is a convex subset of a normed vector space, and Y' the fixed subset of a finite group G as in the final assertion, note that the function $e(v) = |G|^{-1} \sum_{g \in G} gv$ used in the proof of Lemma 5 is nonexpansive:

$$d(e(v), e(w)) = \|e(v) - e(w)\| = \|e(v - w)\| \leq \|v - w\| = d(v, w),$$

and is a retraction of Y onto Y^G .

(iii) This is again a case of suprema of a smaller and a larger set of real numbers.

(iv) The assertion for $X' \subseteq X$ can be seen from the following mapping radii, where subsets of \mathbb{R} are given the induced metric:

$$\text{map-rad}(\{0\}, \{0, 2\}) = 0, \quad \text{map-rad}(\{0, 2\}, \{0, 2\}) = 2, \quad \text{map-rad}(\{0, 1, 2\}, \{0, 2\}) = 0.$$

The assertion for $Y' \subseteq Y$ is shown by the observations

$$\text{map-rad}(\{0, 2\}, \{0\}) = 0, \quad \text{map-rad}(\{0, 2\}, \{0, 2\}) = 2, \quad \text{map-rad}(\{0, 2\}, \{0, 1, 2\}) = 1.$$

Finally, to get the case where Y' is a surjective image of Y , note that we have surjections $\{0, 3\} \rightarrow \{0, 2\} \rightarrow \{0, 1\}$, in **Metr**, and that

$$\text{map-rad}(\{0, 2\}, \{0, 3\}) = 0, \quad \text{map-rad}(\{0, 2\}, \{0, 2\}) = 2, \quad \text{map-rad}(\{0, 2\}, \{0, 1\}) = 1.$$

(With a bit more work, one can construct sets $X, Y_0, Y_1, Y_2 \subseteq \mathbb{R}$ such that each Y_{i+1} is *both* a subset and a surjective image of Y_i , and such that $\text{map-rad}(X, Y_0) < \text{map-rad}(X, Y_1) > \text{map-rad}(X, Y_2)$.) \square

To state consequences of the above results, let us fix some notation.

Definition 8. For $n \geq 0$, n -dimensional Euclidean space, i.e., \mathbb{R}^n with the Euclidean norm, will be denoted \mathbb{E}^n . The class of all Euclidean spaces, $\{\mathbb{E}^n \mid n \geq 0\}$, will be denoted **Euc**.

The class of all normed vector spaces, regarded as metric spaces, will be denoted **NmV**. The class of all convex subsets of normed vector spaces, regarded as metric spaces, will be denoted **Conv**.

The diameter of a metric space X will be defined by $\text{diam}(X) = \sup_{x, y \in X} d(x, y)$.

Corollary 9. If X is a nonempty metric space, then

$$(14) \quad \text{map-rad}(X, \mathbb{E}^1) \leq \text{map-rad}(X, \mathbb{E}^2) \leq \dots \leq \text{map-rad}(X, \mathbb{E}^n) \leq \dots,$$

with supremum $\text{map-rad}(X, \mathbf{Euc})$. Further,

$$\begin{aligned}
(15) \quad \text{diam}(X)/2 &= \text{map-rad}(X, \mathbb{E}^1) \leq \text{map-rad}(X, \mathbf{Euc}) \leq \text{map-rad}(X, \mathbf{NmV}) \\
&\leq \text{map-rad}(X, \mathbf{Conv}) \leq \text{map-rad}(X, \mathbf{Metr}) = \text{rad}_X(X) \leq \text{diam}(X).
\end{aligned}$$

Proof. Since \mathbb{E}^n is the fixed subspace of a reflection of \mathbb{E}^{n+1} , the final assertion of Lemma 7(ii) gives (14). (We could have put “ $0 = \text{map-rad}(X, \mathbb{E}^0) \leq$ ” at the left end of (14); but to do so would complicate some references we want to make to (14) later.) By definition, $\text{map-rad}(X, \mathbf{Euc})$ is the supremum of these values.

To see the initial equality of (15), note on the one hand that under any nonexpansive map $f : X \rightarrow \mathbb{E}^1$, the images of any two points of X are $\leq \text{diam}(X)$ apart, hence $f(X)$ must lie in an interval of length $\leq \text{diam}(X)$, and any interval in \mathbb{E}^1 has radius half its length, so $\text{map-rad}(X, \mathbb{E}^1) \leq \text{diam}(X)/2$. On the other hand, for $x, y \in X$, the function $d(x, -) : X \rightarrow \mathbb{E}^1$ is nonexpansive, and the images of x and y under this map are $d(x, y)$ apart, whence the radius of $f(X)$ is at least half this value. Taking the supremum over all x and y , we get $\text{map-rad}(X, \mathbb{E}^1) \geq \text{diam}(X)/2$.

The next four steps, inequalities among mapping radii, are instances of Lemma 7(iii). In the equality following these, the direction “ \leq ” simply says that nonexpansive maps are radius-nonincreasing, while “ \geq ” is seen by noting that one of the maps in the supremum defining $\text{map-rad}(X, \mathbf{Metr})$ is the identity map of X . The final inequality is immediate. \square

We note in passing some cases where these mapping radii are very easy to evaluate.

Corollary 10. *If a metric space X satisfies $\text{rad}_X(X) = \text{diam}(X)/2$, then all terms of (15) through $\text{rad}_X(X)$ are equal (and hence also equal to all terms of (14)).*

In particular, this is true whenever (i) X is a finite tree, with edges of arbitrary positive lengths, under the arc-length metric, or (ii) X has an isometry ρ with a fixed point 0 such that for every $x \in X$, $d(x, \rho(x)) = 2d(x, 0)$.

Proof. The first sentence is clear from (15). To get the two remaining assertions, it suffices to show in each case that $\text{rad}_X(X) \leq \text{diam}(X)/2$, since (15) gives the reverse inequality.

In case (i), X is compact, so we may choose $x, y \in X$ with $d(x, y) = \text{diam}(X)$. The unique non-self-intersecting path between x and y is isometric to a closed interval, and so has a midpoint p , satisfying $d(x, p) = d(y, p) = \text{diam}(X)/2$; it now suffices to show that $d(z, p) \leq \text{diam}(X)/2$ for all $z \in X$. Consider the unique non-self-intersecting path from p to z . Because X is a tree, that path out of p cannot have nontrivial intersection with both the path from p to x and the path from p to y ; assume it meets the latter only in p . Then the unique non-self-intersecting path from z to y is the union of the path from z to p and the path from p to y , and we know that it has length $\leq \text{diam}(X)$, so subtracting off $\text{diam}(X)/2$, the length of the path from p to y , we conclude that the length of the path from z to p is $\leq \text{diam}(X)/2$, as required.

In case (ii), we have $\text{rad}_X(X) \leq \sup_{x \in X} d(x, 0) = \sup_{x \in X} d(x, \rho(x))/2 \leq \text{diam}(X)/2$. \square

Examples falling under case (ii) above include all centrally symmetric subsets of normed linear spaces containing 0, under the induced metric, and a hemisphere under the geodesic metric.

A less trivial result, now. Recall that in proving the upper bounds on the mapping radii of Lemmas 2, 3 and 4, we in effect chose formal weighted combinations of points of X , and used these to specify convex linear combinations of points of $f(X) \subseteq V$. We abstract this technique below. In the statement of the theorem, as a convenient way to express formal weighted combinations of points of X , we use *probability measures* on X with finite support. (Recall that a probability measure on X is a nonnegative-valued measure μ such that $\mu(X) = 1$, and that μ is said to have support in a set X_0 if $\mu(X - X_0) = 0$. Apologies for the double use of “ d ” below, for the distance function of the metric space and the “ $d\mu$ ” of integration.)

Theorem 11. *Let X be a nonempty metric space. Then*

$$(16) \quad \text{map-rad}(X, \mathbf{Conv}) = \inf_{\mu} \sup_{x \in X} \int_{z \in X} d(x, z) d\mu(z),$$

where the infimum is over all probability measures μ on X with finite support.

Proof. We first prove “ \leq ”, imitating the argument of Lemmas 2, 3 and 4. We must show, for any nonexpansive map $f : X \rightarrow C$, where C is a convex subset of a normed vector-space V , and any probability measure μ on X with finite support, that

$$(17) \quad \text{rad}_C(f(X)) \leq \sup_{x \in X} \int_{z \in X} d(x, z) d\mu(z).$$

For any point x of X , let μ_x denote the probability measure on X with singleton support $\{x\}$. Since the μ of (17) is a probability measure with finite support, it has the form $c_1 \mu_{x_1} + \cdots + c_n \mu_{x_n}$, where x_1, \dots, x_n are points of X , and c_1, \dots, c_n are nonnegative real numbers summing to 1. The point $y = \sum c_i f(x_i)$ lies in C , so by definition of the radius, the left-hand side of (17) is $\leq \sup_{x \in X} d(\sum c_i f(x_i), f(x))$, which by (5) is $\leq \sup_{x \in X} \sum_i c_i d(f(x_i), f(x))$, which, because f is nonexpansive, is $\leq \sup_{x \in X} \sum_i c_i d(x, x_i)$. The sum in this expression is the integral in (17), giving the desired inequality.

In proving the direction “ \geq ” in (16), we may assume the metric space X is bounded, since otherwise it has infinite diameter, in which case (15) tells us that the left hand side of (16) is infinite. Assuming boundedness, we shall display a particular embedding e of X in a convex subset C of a normed vector space U , such that $\text{rad}_C(e(X))$ is greater than or equal to the right-hand side of (16).

Let U be the space of all continuous bounded real-valued functions on X , under the sup norm, let $e : X \rightarrow U$ take each $x \in X$ to the function $d(x, -)$ (this e is easily seen to be nonexpansive) and let C be the convex hull of $e(X)$. Now for $x \in X$, its image $e(x) = d(x, -)$ can be written $y \mapsto \int_z d(y, z) d\mu_x(z)$. Hence an arbitrary $u \in C$, i.e., a convex linear combination of these functions, will have the same form, but with μ_x replaced by a convex linear combination μ of the measures μ_x , i.e., a general probability measure μ on X with finite support. For such a function u , and any $x \in X$, the distance $d(e(x), u)$ in C is the sup norm of $u - e(x)$, which is *at least* the value of $u - e(x)$ at $x \in X$, which is $u(x) - 0 = \int_z d(x, z) d\mu(z)$. The radius of $e(X)$ in C is thus at least the infimum over all μ of the supremum over all x of this integral, which is the right-hand side of (16). \square

Recall that when we obtained our bound (7) on the mapping radius of the 1-skeleton of an octahedron, analogy and good luck led us to the formal linear combination of points of X used in (6) (in effect, a probability measure μ), which turned out to give the optimal bound. In general we ask

Question 12. *Let X be a finite graph with edges of possibly unequal lengths, under the arc-length metric. Must there be a probability measure μ on X with finite support that realizes the infimum of (16)?*

Is there an algorithm for finding such a μ if it exists, or if not, for evaluating (16)?

We cannot expect in general that a measure of the desired sort will have support in the set of *vertices* of the graph X , as happened in Lemma 4. E.g., if X is isometric to a circle with arc-length metric, one can show that a measure μ realizes the infimum of (16) if and only if it gives equal weight to p and q whenever p and q are antipodal points; so if X is, say, an equilateral polygon with an odd number of vertices, μ cannot be concentrated in the vertices.

A class of examples generalizing our octahedral skeleton, which it would be of interest to examine, are the 1-skeleta of cross polytopes [5].

A situation simpler than that of Question 12 is that of a *finite* metric space X . Here the determination of the right-hand side of (16) is a problem in linear programming; whether it has an elegant solution I don’t know. The determination of $\text{map-rad}(X, \mathbb{E}^n)$ for such a space X is, similarly, in principle, a problem in calculus.

In Corollary 10, we saw that the mapping radius is easy to compute for a space that has “a robust center”. The next result shows the same for a space with a pair of “robust antipodes”.

Corollary 13. *Suppose the metric space X has a pair of points p and q such that*

$$(18) \quad (\forall r \in X) \quad d(p, r) + d(r, q) = d(p, q).$$

Then letting $D = d(p, q)$, we have $\text{diam}(X) = D$, and $\text{map-rad}(X, \mathbf{Conv}) = D/2$. Thus, the terms of (15) through $\text{map-rad}(X, \mathbf{Conv})$ all equal $D/2$.

In particular, this is true if X is the 1-skeleton of a regular tetrahedron or of a parallelepiped (in particular, of a cube), with the arc-length metric, or is the 0-skeleton of any of the regular polyhedra other than the tetrahedron, with metric induced by the arc-length metric on the 1-skeleton of that polyhedron.

The property (18) is, of course, inherited by any subspace of X containing p and q .

Proof. For any two points $r, r' \in X$, we have

$$2d(r, r') \leq (d(r, p) + d(p, r')) + (d(r, q) + d(q, r')) = (d(p, r) + d(r, q)) + (d(p, r') + d(r', q)) = 2D,$$

so $d(r, r') \leq D$, whence $\text{diam}(X) = D$. Now let μ be the probability measure giving weight $1/2$ to each of p and q . For this μ , the integral on the right-hand side of (16) has value $D/2$ for all x , hence the supremum of that integral over x is $D/2$, hence (16) shows that $\text{map-rad}(X, \mathbf{Conv}) \leq D/2$, and this forces the terms of (15) through $\text{map-rad}(X, \mathbf{Conv})$ to be equal, as asserted.

For X the 1-skeleton of a regular tetrahedron, we get (18) on taking for p and q the midpoints of two opposite edges. For X the 1-skeleton of a parallelepiped, we can use any two antipodal points (not necessarily vertices. In picturing this case, it may help to note that X is isometric to the 1-skeleton of a *rectangular* parallelepiped.) In the 0-skeleton cases, we use any pair of opposite vertices. In each case, the verification of (18) is reasonably straightforward.

The final sentence is clear. \square

So, for instance, for the 1-skeleta of the tetrahedron and cube of edge 1, the 6-tuples of terms of (15) (not distinguishing terms shown connected by equals-signs) are $(1, 1, 1, 1, 3/2, 2)$ and $(3/2, 3/2, 3/2, 3/2, 3, 3)$ respectively. (The reason the last two numbers are equal for the cube, but distinct for the tetrahedron, is that for the cube, the function $x \mapsto \sup_y d(x, y)$ is 3 for all x , while for the tetrahedron, it ranges from a maximum value 2 at the midpoints of the edges to a minimum value $3/2$ at the vertices. In neither of these cases is the maximum twice the minimum, so neither of them falls under Corollary 10.)

Let us note a curious feature of the construction used in Theorem 11: it has what at first looks like a universal property (part (i) of the next result) but turns out not to be (part (ii)).

Corollary 14 (to proof of Theorem 11). *Let X be a bounded metric space, let U be the space of continuous bounded real-valued functions on X under the sup norm (cf. second half of the proof of Theorem 11), and let $e : X \rightarrow U$ be the map taking each $x \in X$ to the function $d(x, -)$.*

Now let $f : X \rightarrow V$ be any map (in \mathbf{Metr}) from X into a normed vector space V . Then

(i) *For every family of points $x_1, \dots, x_n \in X$, every family c_1, \dots, c_n of nonnegative real numbers summing to 1, and every $x \in X$, one has*

$$(19) \quad d(f(x), \sum_i c_i f(x_i)) \leq d(e(x), \sum_i c_i e(x_i)).$$

However,

(ii) *Given points $x_1, \dots, x_n \in X$, and two families of nonnegative real numbers b_1, \dots, b_n and c_1, \dots, c_n , each summing to 1, it is not necessarily true that*

$$(20) \quad d(\sum_i b_i f(x_i), \sum_i c_i f(x_i)) \leq d(\sum_i b_i e(x_i), \sum_i c_i e(x_i)).$$

Thus, the convex hull of $e(X)$ need not admit a map (in \mathbf{Metr}) to the convex hull of $f(X)$ making a commuting triangle with e and f .

Proof. (i) may be seen by combining the calculations of the last sentence of the proof of the “ \leq ” direction of Theorem 11, which shows that $d(f(x), \sum c_i f(x_i)) \leq \sum c_i d(x, x_i)$, and the end of the proof of the “ \geq ” direction, which, by evaluating $e(x_i)$ and $e(x)$ as elements of the function-space U at the point x , shows that $d(e(x), \sum c_i e(x_i)) \geq \sum c_i d(x, x_i)$.

To get (ii), let X again be a circle of circumference 4 with arc-length metric, and let $x_0, x_1, x_2, x_3 \in X$ be four points equally spaced around it. Note that for any $u \in X$, we have $d(x_0, u) + d(x_2, u) = 2 = d(x_1, u) + d(x_3, u)$. Hence if we choose the b_i and c_i so that the right-hand-side of (20) is $d((e(x_0) + e(x_2))/2, (e(x_1) + e(x_3))/2)$, we see that this value is 0. On the other hand, if we map X into \mathbb{E}^1 by $f(x) = 1 - \max(d(x_0, x), 1)$, then of the $f(x_i)$, only $f(x_0)$ is nonzero, so the left-hand side is not 0, so (20) fails. \square

There are, in fact, a different normed vector space U and mapping $e : X \rightarrow U$ for which the universal property of (20) does hold [20, Theorem 2.2.4]; we discuss this construction in an appendix, §6.

3 Some explicit mapping radii.

A classical result of H. E. W. Jung, [14] is, in effect, an evaluation of the mapping radius in \mathbb{E}^n of a very simple metric space.

Theorem 15 (after Jung [14]). *Let D_∞ denote an infinite metric space in which the distances between distinct points are all 1. (The cardinality does not matter as long as it is infinite.) Then the values of $\text{map-rad}(D_\infty, \mathbb{E}^n)$ for $n = 0, 1, 2, \dots$ are*

$$(21) \quad 0 < 1/2 < 1/\sqrt{3} < \dots < \sqrt{n/(2(n+1))} < \dots$$

Hence, $\text{map-rad}(D_\infty, \mathbf{Euc}) = 1/\sqrt{2}$.

Likewise, for any positive integer m , if we let D_m be an m -element metric space with all pairwise distances 1, then for every $n \geq 0$,

$$(22) \quad \text{map-rad}(D_m, \mathbb{E}^n) = \sqrt{r/(2(r+1))}, \quad \text{where } r = \min(m-1, n).$$

Hence, $\text{map-rad}(D_m, \mathbf{Euc}) = \sqrt{(m-1)/(2m)}$.

Summary of proof. The main result of [14] is that every subset of \mathbb{E}^n of diameter ≤ 1 has radius $\leq \sqrt{n/(2(n+1))}$. This gives $\text{map-rad}(D_\infty, \mathbb{E}^n) \leq \sqrt{n/(2(n+1))}$. On the other hand, the $n+1$ vertices of the n -simplex of edge 1 in \mathbb{E}^n form a subset of radius exactly $\sqrt{n/(2(n+1))}$, and clearly D_∞ can be mapped onto that set, establishing equality. Taking the limit of this increasing sequence as $n \rightarrow \infty$, one gets $\text{map-rad}(D_\infty, \mathbf{Euc}) = 1/\sqrt{2}$.

Clearly, the hypothesis $m > n$ works as well as $m = \infty$ in concluding as above that $\text{map-rad}(D_m, \mathbb{E}^n) = \sqrt{n/(2(n+1))}$. For $m \leq n$, on the other hand, any image of D_m in \mathbb{E}^n lies in an affine subspace that can be identified with \mathbb{E}^{m-1} , so in that case we get $\text{map-rad}(D_m, \mathbb{E}^n) = \text{map-rad}(D_m, \mathbb{E}^{m-1}) = \sqrt{(m-1)/(2m)}$. Combining these results, we get (22) and the final conclusion. \square

The inequalities (21) show that all steps of (14) can be strict. Can the steps of (15) likewise be made strict? The one for which I do not know the answer is

$$(23) \quad \text{map-rad}(X, \mathbf{NmV}) \leq \text{map-rad}(X, \mathbf{Conv}).$$

I thought at first that equality was immediate: that for a map f of X into a convex subset C of a normed vector space V , one always had $\text{rad}_V(f(X)) = \text{rad}_C(f(X))$. However, this is not so. For example, let X be the 3-point metric space D_3 of Theorem 15, call its points x_0, x_1, x_2 , and consider the embedding $e : X \rightarrow U$ of the proof of Theorem 11 and the statement of Corollary 14. U can be described as \mathbb{R}^3 under the sup norm; let C be the convex hull in U of

$$(24) \quad e(X) = \{(0, 1, 1), (1, 0, 1), (1, 1, 0)\}.$$

Then Lemma 7(ii) (in particular, the final sentence) tells us that $\text{rad}_C(e(X))$ is the common distance of the three points of $e(X)$ from the unique point of C invariant under cyclic permutation of the coordinates, namely $(2/3, 2/3, 2/3)$. We see that this common distance is $2/3$ (because each member of $e(X)$ has a zero coordinate), so $\text{rad}_C(e(X)) = 2/3$ (and by Theorem 11, this is $\text{map-rad}(X, \mathbf{Conv})$). On the other hand, in U , the point $(1/2, 1/2, 1/2)$ has distance $1/2$ from each point of $e(X)$, so $\text{rad}_U(e(X)) \leq 1/2$.

This does not, however, prove that this X satisfies $\text{map-rad}(X, \mathbf{NmV}) < \text{map-rad}(X, \mathbf{Conv})$; for the above map $e : X \rightarrow U$ need not maximize the radius of its image among all maps of X into normed vector spaces. Indeed, let us apply a translation that carries the plane in U spanned by $e(X)$ to a plane through the origin, for instance translation by $(-2/3, -2/3, -2/3)$. Then e composed with that translation gives a map f of X into that plane,

$$(25) \quad U_0 = \{(x, y, z) \in U \mid x + y + z = 0\} \quad \text{with the norm induced from } U,$$

and we see that $\text{rad}_{U_0}(f(X)) = \text{rad}_C(e(X)) = 2/3$, and so conclude that for this space X , equality holds in (23).

Digressing for a moment, let us note a curious consequence of this example.

Lemma 16. *Let U be \mathbb{R}^3 under the sup norm, and $U_0 \subseteq U$ be defined by (25). Then there is no isometric reflection $U \rightarrow U$ having U_0 as its fixed subspace. In fact, no finite group of affine isometries of any normed vector space W containing U has U_0 as its fixed subspace.*

Proof. Suppose $W \supseteq U$ had a finite group G of affine isometries with fixed subspace U_0 . The first sentence of Lemma 7(ii) gives $\text{rad}_W(e(X)) \leq \text{rad}_U(e(X))$, and we have seen that the latter is $< \text{rad}_{U_0}(e(X))$; but Lemma 5 says $\text{rad}_W(e(X)) = \text{rad}_{U_0}(e(X))$. \square

Can the trick we used above, of translating our convex set C so that the affine space it spans becomes a vector subspace, be made to give a general proof of equality in (23)? A little thought shows that this is unlikely: The usefulness of that trick depends on the affine span of C being a proper subset of U to begin with; but that property of a convex subset C of a vector space is not “robust”: By “thickening” such a convex set C slightly, one can make its affine span all of U , without losing the property that the radius of a spanning subset $X \subseteq C$ with respect to C is greater than its radius with respect to U . And, indeed, the following example, suggested by these considerations, shows that for a different choice of X , the set $e(X)$ of Theorem 11 and Corollary 14 has smaller radius in its affine span than in its convex hull.

Let X be a 6-point metric space $\{x_0, x_1, x_2, y_0, y_1, y_2\}$, where the x_i have pairwise distances 1, each y_i has distance $1/2$ from x_i , and the distance between other pairs of points is the length of the shortest path between them via these links. Thus, for $i \neq j$,

$$(26) \quad d(x_i, x_j) = 1, \quad d(x_i, y_i) = 1/2, \quad d(x_i, y_j) = 3/2, \quad d(y_i, y_j) = 2.$$

Again let U be the space of all real-valued functions on X under the sup norm (continuity and boundedness are vacuous since X is finite), let $e : X \rightarrow U$ be the map taking each $x \in X$ to the function $d(x, -)$, and let C be the convex hull of $e(X)$. Let U_1 denote the affine span of C . In computing the radius of $e(X)$ with respect to any of C , U_1 , or U , Lemma 5 tells us that it suffices to consider elements y invariant under cyclic permutation of the subscript set $\{0, 1, 2\}$. These elements form the 2-dimensional subspace of U spanned by $p_x = (e(x_0) + e(x_1) + e(x_2))/3$ and $p_y = (e(y_0) + e(y_1) + e(y_2))/3$, which one finds are described by

$$p_x(x_i) = 2/3, \quad p_x(y_i) = 7/6; \quad p_y(x_i) = 7/6, \quad p_y(y_i) = 4/3.$$

The points of C invariant under our group are the *convex* linear combinations of p_x and p_y , and we find that the infimum defining $\text{rad}_C(e(X))$ is achieved by the element p_x , which satisfies $d(p_x, e(x_i)) = 2/3$, $d(p_x, e(y_i)) = 7/6$, so $\text{rad}_C(e(X)) = 7/6$. The points invariant under our group in the larger set U_1 are the *affine* combinations of p_x and p_y , and we find that among these, $q = 2p_x - p_y$, with values

$$q(x_i) = 1/6, \quad q(y_i) = 1,$$

satisfies $d(q, e(x_i)) = 5/6$, $d(q, e(y_i)) = 1$. Hence $\text{rad}_{U_0}(e(X)) \leq 1 < 7/6 = \text{rad}_C(e(X))$.

Nevertheless, this X again has equality in (23). For if we map it into the space \mathbb{R}^2 with the norm having a regular hexagon as unit ball, by mapping the x_i to the vertices of the triangle described in the paragraph preceding Lemma 4, and the y_i to the turning-points of the loops that we attached to those vertices, we see, as we did there, that the radius of the image is precisely $7/6$.

So we ask

Question 17. *Are there any metric spaces X for which the inequality (23) is strict?*

Some further observations on the phenomenon which keeps that equality from being “trivially” true (paragraph after (23) above) are given in an appendix, §7 below.

Returning to (15), examples where the steps other than the refractory step (23) are strict are easily found. All but the last are given by $X = D_3$: I claim that here the 6-tuple of terms connected by “ \leq ” in (15) is $(1/2, 1/\sqrt{3}, 2/3, 2/3, 1, 1)$. The first and the last values are clear; the value $\text{map-rad}(D_3, \mathbf{Euc}) = 1/\sqrt{3}$ follows from Theorem 15, and the values $\text{map-rad}(D_3, \mathbf{NmV}) = \text{map-rad}(D_3, \mathbf{Conv}) = 2/3$ were established above in the paragraphs containing (25) and (24) respectively. For strict inequality at the final step of (15), $\text{rad}_X(X) \leq \text{diam}(X)$, one can use any nontrivial instance of Corollary 10; for instance, the unit interval $[0, 1]$, for which that corollary shows that the 6-tuple in question is $(1/2, 1/2, 1/2, 1/2, 1/2, 1)$.

Turning back to mapping radii in Euclidean spaces, a family of questions suggested by Theorem 15 is

Question 18. *For $n \geq 2$, what can one say about the set of nonnegative real numbers that can be written $\text{map-rad}(X, \mathbb{E}^n)$ for finite metric spaces X in which all distances are integers?*

Are all such real numbers “constructible”, i.e., obtainable from the rational numbers by a finite sequence of square roots and ring operations?

Is this set well-ordered for each n ? (It has a smallest element 0, and a next-to-smallest element $1/2$.)

Does this set change if “finite metric spaces $X \dots$ ” is weakened to “bounded metric spaces $X \dots$ ”?

For $m < n$, can one assert any inclusion between the sets of mapping radii into \mathbb{E}^m , and into \mathbb{E}^n ? Are there values that occur as $\text{map-rad}(X, \mathbf{Euc})$ for some X , but not as $\text{map-rad}(X', \mathbb{E}^n)$ for any X' and n ? (E.g., can $1/\sqrt{2}$ be written in the latter form?)

We end this section with an observation made in [9] for the spaces \mathbb{E}^n , which in fact holds for closed convex subsets of arbitrary finite-dimensional normed spaces.

Lemma 19 (cf. [9, Prop. 29, p.14, and 2nd paragr. of p.46]). *If C is a closed convex subset of a normed vector space V of finite dimension n , and A a subset of C with $> n$ elements, then $\text{rad}_C(A) = \sup_{A_0} \text{rad}_C(A_0)$, where A_0 runs over the $n+1$ -element subsets of A .*

Proof. “ \geq ” is clear; so it suffices to show that if for some real number r , each A_0 is contained in a closed ball of radius r centered at a point of C , then so is A . Now for each $a \in A$, the set of $v \in C$ such that a lies in the closed ball in C of radius r about v is the closed ball in C of radius r about a , hence a compact convex subset of V . To say that a set A_0 is contained in a closed ball of radius r centered at a point of C is to say that the intersection of these sets, as a runs over A_0 , is nonempty. By Helly’s Theorem ([11], [6]), if a family of compact convex subsets of \mathbb{R}^n has the property that every system of $n+1$ members of this family has nonempty intersection, then so does the whole family, which in this case means that all of A is contained in a ball of the indicated sort, as desired. \square

The above lemma does not imply the corresponding statement for mapping radii. For example, let $X = \{x, y_0, y_1, y_2\}$, where x has distance $1/2$ from each of the y_i , and these have distance 1 from each other. The maximum of the mapping radii in \mathbb{E}^2 of 3-element subsets of X is $\text{map-rad}(\{y_0, y_1, y_2\}, \mathbb{E}^2) = 1/\sqrt{3}$, the radius of an equilateral triangle of side 1. But $\text{map-rad}(X, \mathbb{E}^2) \leq \text{rad}_X(X) = 1/2$.

On the other hand, for this example, $\text{map-rad}(X, \mathbb{E}^2)$ can be described as the infimum over $p \in X$ of the supremum of $\text{map-rad}(X_0, \mathbb{E}^2)$ over all 3-element subsets X_0 of X containing p . So we ask

Question 20. *Does there exist, for every positive integer n , a positive integer N and a formula that, for every metric space X of $\geq N$ elements and every normed vector space V , expresses $\text{map-rad}(X, V)$ in terms of suprema, infima, and the numbers $\text{map-rad}(X_0, V)$ for N -element subsets $X_0 \subseteq X$?*

4 Realizability of mapping radii.

For a subset A of a metric space Y , let us say that $\text{rad}_Y(A)$ is *realized* if the infimum in the definition (2) of that expression is attained, that is, if there exists $y \in Y$ such that A is contained in the ball of radius $\text{rad}_Y(A)$ about y .

Likewise, for metric spaces X and Y , let us say that $\text{map-rad}(X, Y)$ is realized if the supremum in the definition of that expression is attained; that is, if there exists an $f : X \rightarrow Y$ such that $\text{rad}_Y(f(X)) = \text{map-rad}(X, Y)$. (This does not presume that $\text{rad}_Y(f(X))$ is realized.)

Lemma 21. *Let X and Y be nonempty metric spaces.*

- (i) *If Y is compact, then for any subset $A \subseteq Y$, $\text{rad}_Y(A)$ is realized.*
- (ii) *If X and Y are both compact, then $\text{map-rad}(X, Y)$ is realized.*

However

- (iii) *For X compact and Y bounded and complete, or for X bounded and complete and Y compact, $\text{map-rad}(X, Y)$ may fail to be realized.*

Proof. (i) follows from the fact that for bounded A , $\sup_{a \in A} d(a, y)$ is a continuous function of y , hence assumes a minimum on Y .

To get (ii), we note that $\mathbf{Metr}(X, Y)$ is a closed subset of the function space Y^X , which is compact because Y is, so $\mathbf{Metr}(X, Y)$ is compact in the function topology. We would like to say that the real-valued map on this space given by $f \mapsto \text{rad}_Y(f(X))$ is continuous, and hence assumes a maximum. For general X , this continuity does not hold, as will follow from the second statement of (iii); but I claim that it holds if X is compact. For given $f \in \mathbf{Metr}(X, Y)$ and $\varepsilon > 0$, compactness allows us to cover X by finitely many open balls of radius $\varepsilon/3$, say centered at x_1, \dots, x_n . Consider the neighborhood of f in $\mathbf{Metr}(X, Y)$ given by

$$U = \{g \in \mathbf{Metr}(X, Y) \mid d(f(x_i), g(x_i)) < \varepsilon/3 \text{ } (i = 1, \dots, n)\}.$$

Taking any $x \in X$ and $y \in Y$, note that there exists i such that $d(x_i, x) < \varepsilon/3$; hence for $g \in U$,

$$\begin{aligned} |d(f(x), y) - d(g(x), y)| &\leq d(f(x), g(x)) \leq d(f(x), f(x_i)) + d(f(x_i), g(x_i)) + d(g(x_i), g(x)) \\ &\leq \varepsilon/3 + \varepsilon/3 + \varepsilon/3 = \varepsilon. \end{aligned}$$

Thus, the two functions associating to every $y \in Y$ the numbers $\sup_{x \in X} d(f(x), y)$ and $\sup_{x \in X} d(g(x), y)$ differ everywhere by $\leq \varepsilon$, whence the infima of these functions, $\text{rad}_Y(f(X))$ and $\text{rad}_Y(g(X))$ differ by $\leq \varepsilon$, giving continuity of $f \mapsto \text{rad}_Y(f(X))$, which, as noted above, yields (ii).

(iii) For an example with X but not Y compact, let $X = D_2$, i.e., a space consisting of two points at distance 1 apart, and let $Y = \{y_2, y_3, \dots, y_n, \dots\} \cup \{z\}$, with $d(y_m, y_n) = 1$ ($m \neq n$) and $d(y_n, z) = 1 - 1/n$. Note that the radius in Y of a point-pair $\{z, y_n\}$ or $\{y_m, y_n\}$ with $m < n$ is $1 - 1/n$. Now $\mathbf{Metr}(X, Y)$ consists of *all* set-maps $X \rightarrow Y$, and it follows from the above calculation that $\text{map-rad}(X, Y) = \sup_n (1 - 1/n) = 1$, but that this value is not achieved. (If we had not specified that Y should be complete, we could have used the simpler example, $X = D_2$, $Y = [0, 1)$.)

For an example with Y but not X compact, let $X = \{x_2, x_3, \dots, x_n, \dots\}$, with $d(x_{2n}, x_{2n+1}) = 2 - 1/n$, and all other pairs of distinct points having distance 1; and let $Y = [0, 2] \subseteq \mathbb{E}^1$. Note that if a map $X \rightarrow Y$ is to have radius $> 1/2$, it must send some pair of points to values differing by > 1 , and by our metric on X , these two points must have the forms x_{2n}, x_{2n+1} . Since all other points have distance 1 from these two, the images of all other points must fall within the interval between their images. Hence the image of our map falls within an interval of length $\leq 2 - 1/n$ for some positive n , i.e., of length < 2 , and hence of radius < 1 . But such images can have radii arbitrarily close to 1, again giving a mapping radius that is not realized. \square

Corollary 22. *Suppose Y is a metric space in which every closed bounded subset is compact. Then*

- (i) *For every bounded nonempty subset $A \subseteq Y$, $\text{rad}_Y(A)$ is realized.*
- (ii) *If the isometry group of Y is transitive, or more generally, if Y has a bounded subset which meets every orbit of that group, then for every compact nonempty metric space X , $\text{map-rad}(X, Y)$ is realized.*

Proof. (i) Let $\text{rad}_Y(A) = r$, choose any $a_0 \in A$, and let Y' be the closed ball of any radius $r' > r$ about a_0 in Y . By assumption Y' is compact. We see that $A \subseteq Y'$, and that any point $y \in Y$ with $\sup_{a \in A} d(y, a) \leq r'$ must lie in Y' . Since $\inf_{y \in Y} \sup_{a \in A} d(y, a) = r$, the space Y contains points y for which $\sup_{a \in A} d(y, a)$ comes arbitrarily close to r ; hence it will contain points for which that value is arbitrarily close to r and is $\leq r'$. Points with this latter property lie in Y' , whence $\text{rad}_{Y'}(A)$ is also equal to r , and applying part (i) of the preceding lemma to Y' gives the desired conclusion.

(ii) Suppose every orbit of the isometry group of Y meets the closed ball of radius c about $y_0 \in Y$, and let x_0 be any point of X . Then every $f : X \rightarrow Y$ may be adjusted by an isometry of Y (which will preserve the radius of $f(X)$) so that we get $d(f(x_0), y_0) \leq c$, and after this adjustment, $f(X)$ will lie in the closed ball of radius $c + \text{diam}(X)$ about y_0 . Letting Y' denote the closed ball of any radius $r' > c + \text{diam}(X)$ about y_0 , we see as in the proof of (i) that the radii of these image sets $f(X)$ in Y' will equal their radii within Y , and applying part (ii) of the preceding lemma with Y' for Y , we get the desired conclusion. \square

5 Related literature (and one more question).

Lemma 2 above, determining the mapping radius of a circle in a normed vector space V , occurs frequently in the literature (with \mathbb{E}^3 or \mathbb{E}^n for V) as an offshoot of the proof of Fenchel's Theorem, the statement

that the total curvature of a closed curve C in \mathbb{E}^3 is at least 2π , with equality only when C is planar and convex [7, Satz I]. To prove that theorem, Fenchel noted that this total curvature is the length of the curve in the unit sphere S^2 traced by the unit tangent vector to C , and that that curve cannot lie wholly in an open hemisphere of S^2 (nor in a closed hemisphere unless C is planar). He completed the proof by showing [7, Satz I'] that a closed curve of length $< 2\pi$ (respectively, equal to 2π) in S^2 must lie in an open hemisphere (respectively, must either lie in an open hemisphere or be a union of two great semicircles). In our language, this says that a circle of circumference $< 2\pi$, made a metric space using arc-length, has mapping radius $< \pi/2$ in S^2 (and, along with some additional information, that the circle of arc-length exactly 2π has mapping radius $\pi/2$).

Subsequent authors [3], [4, Lemma on p.30], [13], [16], [18], [19] gave simpler proofs of Fenchel's Satz I' (similar to our proof of Lemma 2), and/or generalized that result from S^2 to S^n , and/or obtained the more precise result that the mapping radius of a circle of any length $L \leq 2\pi$ in S^n is $L/4$, and/or noted that the same method gives the analogous result with \mathbb{E}^n , or indeed any of a large class of geometric structures, in place of S^n .

The last-mentioned generalizations were based on the observation that the concept of the *midpoint* of a pair of points can be defined, and behaves nicely, in many geometric contexts. I do not know whether more general convex linear combinations, such as we used in (5) and in the proof of Theorem 11, can be defined outside the context of vector spaces so as to behave nicely; hence the emphasis in this note on vector spaces and their convex subsets. A. Weinstein (personal communication) suggests that an approach to “averaging” of points introduced by Cartan and developed further in [21] might serve this function.

The results on closed curves of length L in the unit sphere cited above all take $L \leq 2\pi$. If we write S_L^1 for a circle of circumference L , and S^n for the unit n -sphere (of circumference 2π) with geodesic distance as metric, it is clear that the result $\text{map-rad}(S_L^1, S^n) = L/4$ cannot be expected to hold when $L > 2\pi$; but it would be interesting to investigate how that mapping radius does behave as a function of L . For all L , $\text{map-rad}(S_L^1, S^n) < \pi$, since a curve of fixed length cannot come arbitrarily close to every point of S_n , and if it misses the open disk of geodesic radius r about a point p , then it is contained in the closed disc of geodesic radius $\pi - r$ about the antipodal point.

Many of the papers referred to above also consider non-closed arcs, i.e., also study $\text{map-rad}([0, L], S^n)$, and prove that for $L \leq \pi$, this equals $L/2$. Again, the case of larger L would be of interest. So we ask

Question 23. *For fixed $n > 1$, how does $\text{map-rad}(S_L^1, S^n)$ behave for $L > 2\pi$, and how does $\text{map-rad}([0, L], S^n)$ behave for $L > \pi$, as functions of L ?*

For instance, are these two functions piecewise analytic?

It seems likely that there will be ranges of values of L in which different configurations of a closed curve or arc of length L give maximum radius, and that the functions will be analytic within each such range. (I conjecture that for all L between 2π and a value somewhat greater than 3π , $\text{map-rad}(S_L^1, S^n)$ will be realized by a “3-peaked crown”, consisting of 6 arcs of great circles, with midpoints equally spaced along a common equator.)

Many papers in this area also consider the smallest “box” – in various senses – into which one can fit all curves, or closed curves, of unit length [3] [10] [17] (or, in [8], all point-sets of unit diameter). These do not translate into statements about our concept of mapping radius for two reasons. First, they deal with arc length in the Euclidean metric, but with “boxes” which, though they could in many cases be considered closed balls in another metric, are not balls in the Euclidean metric; and our formalism of mapping radius does not look at more than one metric on Y at a time. Second, they generally allow rotations as well as translations in fitting the box around the curve; while in looking at radii, we only have one closed ball of each radius centered at a given point.

6 Appendix: The Arens-Eells space of X .

I mentioned at the end of §2 that every metric space X admits an embedding in a normed vector space U having the universal property that Corollary 14(ii) showed that the embedding we were considering there did *not* have. The construction with this property was introduced by Arens and Eells [1], and its universal property noted by Weaver [20, Theorem 2.2.4], who calls it the Arens-Eells space of X . Weaver is there

interested in this space as a pre-dual to the Banach space of Lipschitz functions on X . I will sketch here a motivation for the same object in terms of its universal property. (My description will also make a couple of technical choices different from those of [1] and [20].)

Fixing a metric space X , let us consider first an arbitrary nonexpansive map f of X into a normed vector space V , and ask, as a sample question: For points $x_1, x_2, x_3, x_4 \in X$, what can we say about $\|f(x_1) + f(x_2) - f(x_3) - f(x_4)\|$?

Clearly, this will be bounded above by $\|f(x_1) - f(x_3)\| + \|f(x_2) - f(x_4)\| \leq d(x_1, x_3) + d(x_2, x_4)$. The other way of pairing the terms similarly gives the bound $d(x_1, x_4) + d(x_2, x_3)$. Hence

$$(27) \quad \|f(x_1) + f(x_2) - f(x_3) - f(x_4)\| \leq \min(d(x_1, x_3) + d(x_2, x_4), d(x_1, x_4) + d(x_2, x_3)).$$

For a less straightforward case, consider $\|3f(x_1) + f(x_2) - 2f(x_3) - 2f(x_4)\|$. There is no longer a way of pairing off terms whose coefficients are the same except for sign. There are, however, ways of breaking up our expression into a linear combination of differences; and with a little experimentation, one finds that all ways of doing so are convex combinations of two extreme decompositions. These two cases lead to the bound

$$(28) \quad \|3f(x_1) + f(x_2) - 2f(x_3) - 2f(x_4)\| \leq \min(2d(x_1, x_3) + d(x_1, x_4) + d(x_2, x_4), d(x_1, x_3) + 2d(x_1, x_4) + d(x_2, x_3)).$$

We will not stop to prove that (27) and (28) are best possible bounds; let us simply observe that these considerations suggest that the norm of such a linear combination of images of points of X under a *universal* map $e : X \rightarrow U$ should be given by an infimum of linear combinations of the numbers $d(x, y)$ ($x, y \in X$) with nonnegative real coefficients, the infimum being taken over all such linear combinations which, when each $d(x, y)$ is replaced by $e(x) - e(y)$, give the chosen expression.

An obvious problem is that the only expressions we get in this way are those in which the sum of the coefficients is 0. This difficulty is intrinsic in the situation: We cannot in fact construct a nonexpansive map of X into a normed vector space which is universal in the obvious sense with respect to nonexpansive maps, because, though the hypothesis of nonexpansivity bounds the distances between images of different points of X , it does not bound the distances between points of X and 0, so such a universal property would force the images of points of X to have infinite norm.

What we can get, rather, is a map e of X into a vector space U , and a norm on the subspace U_0 of linear combinations of images of points of X with coefficients summing to 0, such that for all $x, y \in X$, one has $\|e(x) - e(y)\| \leq d(x, y)$, with the universal property that given any nonexpansive map f of X into a normed linear space V , there exists a unique $g : U \rightarrow V$ which is nonexpansive on U_0 , and satisfies $f = ge$. Observe that the norm on U_0 induces a metric on each coset of U_0 ; in particular, on the coset U_1 of elements in which the sum of all coefficients is 1, which is the affine span of the image of X ; this allows one to translate the above universal property as condition (20).

(Weaver's answer to the same difficulty is to use metric spaces with basepoint, and basepoint-respecting maps, the basepoint of a vector space always being 0. This approach has the advantage of giving a universal property in the conventional sense, with both U and V belonging to the category of normed vector spaces. However, it requires one to make a possibly unnatural choice of basepoint in X ; changes in that choice induce isometries on the universal space which, though affine, are not linear. The approach I find most appealing is to regard what I have called U_1 as a "normed affine space", that is, a set with a simply transitive group of "translation" maps by elements of a normed vector space, and note that it has a genuine universal property in the category of normed affine spaces; but the development of that concept would be an excessive excursion for this appendix. Still another approach would be to work with "normed" vector spaces where the norm is allowed to take on the value $+\infty$. But, returning to the construction sketched above, it is immediate that the Arens-Eells space of X as described in [20], and my U_0 , are isometrically isomorphic, so below I will quote results of Weaver's, tacitly restated for this version of the construction.)

The details, now: let U be the vector space of all real-valued (not necessarily nonnegative) measures μ on X with finite support, and as before, for each $x \in X$ let μ_x be the probability measure with support $\{x\}$; thus $\{\mu_x \mid x \in X\}$ is a basis of U . Let $U_0 \subseteq U$ denote the subspace of measures μ satisfying $\mu(X) = 0$. Let W similarly denote the space of all real-valued measures on $X \times X$ with finite support; for each $(x, y) \in X \times X$ let $\nu_{x,y}$ be the probability measure with support $\{(x, y)\}$, and let $W_+ \subseteq W$ be the

cone of nonnegative linear combinations of the $\nu_{x,y}$, i.e., the nonnegative-valued measures in W . Finally, let $D : W \rightarrow U_0$ be the surjective linear map sending each $\nu_{x,y}$ to $\mu_x - \mu_y$. Then we define our norm on U_0 by

$$(29) \quad \|\mu\| = \inf_{\nu \in W_+, D(\nu)=\mu} \int_{(x,y) \in X \times X} d(x,y) d\nu.$$

It is easy to verify that this indeed gives a norm with the indicated universal property. The one point that is not immediately obvious is that (29) is a norm rather than a pseudonorm; i.e., is nonzero for nonzero $\mu \in U_0$. To get this, one first checks the desired universal property in the wider context of pseudonormed vector spaces, then notes that for every nonzero $\mu = \sum a_i \mu_{x_i} \in U_0$, one can find a nonexpansive map $f : X \rightarrow \mathbb{R}$ which is zero at all but one of the x_i , say x_{i_0} , from which it follows by the universal property that $\|\mu\| \geq |\sum a_i f(x_i)| = |a_{i_0} f(x_{i_0})| > 0$.

Weaver [20, Theorem 2.3.7(b)] shows that the infimum in (29) is always attained, and in fact, by a ν whose “support” in X (the set of points which appear as x or y in terms $\nu_{x,y}$ in the expression for ν) coincides with the support of μ (the set of x such that μ_x appears in the expression for μ).

Let us strengthen this result a bit. We will use the following notation and terminology.

Given $\nu = \sum_{j \in J} b_j \nu_{x_j, y_j} \in W$ (where all $b_j \neq 0$, and the pairs (x_j, y_j) are distinct), let $\Gamma(\nu)$ be the directed graph having for vertices all points of X , and for edges the finitely many pairs (x_j, y_j) ($j \in J$). Let us define the *positive support* of a directed graph Γ as the set of vertices which are initial points of edges, and its *negative support* as the set of vertices which are terminal points of edges. For $\nu \in W$, we will also call the positive and negative supports of $\Gamma(\nu)$ the positive and negative supports of ν . On the other hand, for $\mu = \sum_I a_i \mu_{x_i} \in U_0$, let us define its positive support to be $\{x_i \mid a_i > 0\}$, and its negative support to be $\{x_i \mid a_i < 0\}$. These are clearly disjoint. Note that for $\nu \in W_+$, the positive support of $D(\nu)$ is contained in the positive support of ν , and contains (at least) all elements thereof that are not also in the negative support of ν ; and the negative support of $D(\nu)$ has the dual properties.

When we speak of a *cycle* in a directed graph, we shall mean a cycle in the corresponding undirected graph; we shall also understand that in a cycle no vertex is traversed more than once. Note that a cycle of length 1 in $\Gamma(\nu)$ can only arise when a term $\nu_{x,x}$ has nonzero coefficient in ν , while a cycle of length 2, i.e., the presence of two edges between x and y , can only occur if $\nu_{x,y}$ and $\nu_{y,x}$ both have nonzero coefficient. But a cycle of length $n > 2$ with a given sequence of vertices may arise in any of 2^n ways, depending on orientations of the edges.

Lemma 24. *Let $\mu \in U_0$.*

Then the infimum of (29) is attained by an element $\nu \in W_+$ (not necessarily unique) whose positive and negative supports coincide with the positive and negative supports of μ respectively, and whose graph $\Gamma(\nu)$ has no cycles.

Moreover, for any directed graph Γ without cycles, there is at most one $\nu \in W$ having $D(\nu) = \mu$ and $\Gamma(\nu) \subseteq \Gamma$; so in particular, no two elements ν as in the preceding paragraph have the same graph.

Proof. As mentioned, Weaver proves the existence of $\nu \in W_+$ with $D(\nu) = \mu$ which achieves the minimum (29) and has the same support as μ . Let ν be chosen, first, to have these properties; second, among such elements, to minimize the total number of edges in $\Gamma(\nu)$, and finally, to minimize the sum of the coefficients of all the $\nu_{x,y}$ in its expression. This last condition is achievable because the set of elements of W_+ which are linear combinations of a given finite family of the $\nu_{x,y}$, and for which the coefficients of these elements are all \leq some constant, is compact; so after finding some ν with $D(\nu) = \mu$ which achieves the minimum (29), has the same support as μ , and minimizes the number of edges in $\Gamma(\nu)$, we may restrict our search for elements also minimizing the coefficient-sum to the compact set of elements with every coefficient less than or equal to the coefficient-sum of the element we have found.

Suppose, now, that $\Gamma(\nu)$ has a cycle. Thus, we have distinct vertices p_1, \dots, p_k , and for each $j \in \{1, \dots, k\}$ a term $\nu_{p_j, p_{j+1}}$ or ν_{p_{j+1}, p_j} occurring with positive coefficient in ν . (If both $\nu_{p_j, p_{j+1}}$ and ν_{p_{j+1}, p_j} occur we choose one arbitrarily. Subscripts, of course, are taken modulo k . If $k = 2$ we make sure that our chosen terms are distinct, one being ν_{p_1, p_2} and the other ν_{p_2, p_1} .) For each $j \in \{1, \dots, k\}$ let us now define $\nu'_{p_j, p_{j+1}}$ to be $\nu_{p_j, p_{j+1}}$ if that is our j th term, or $-\nu_{p_{j+1}, p_j}$ if our j th term is ν_{p_{j+1}, p_j} , and let $\nu' = \sum_j \nu'_{p_j, p_{j+1}} \in W$. In general, $\nu' \notin W_+$, but for all $\lambda \in \mathbb{R}$ near enough to 0, we have $\nu + \lambda \nu' \in W_+$, since the relevant coefficients in ν are strictly positive. Also, $D(\nu') = 0$, so $D(\nu + \lambda \nu') = D(\nu) = \mu$.

Note that $\int_{(x,y) \in X \times X} d(x,y) d(\nu + \lambda \nu')$ is an affine function of λ . Hence it must be constant, otherwise, using small λ of appropriate sign, we would get a contradiction to the assumption that ν achieves the minimum of (29); so all the elements $\nu + \lambda \nu'$ achieve this same minimum. Now some choice of λ will cause $\lambda \nu'$ to exactly cancel the smallest of the coefficients among our chosen terms $\nu_{p_j, p_{j+1}}$ or ν_{p_{j+1}, p_j} in ν . Thus, $\nu + \lambda \nu'$ contradicts the minimality assumption on the number of edges in $\Gamma(\nu)$. This contradiction shows that $\Gamma(\nu)$ has no cycles.

Next, let us compare the positive and negative supports of ν with those of μ . We have chosen ν so that its support, namely the union of its positive and negative supports, coincides with the support of μ ; and the positive and negative supports of ν will each *contain* the corresponding support of μ , since $\mu = D(\nu)$. So if these inclusions are not equalities, we must have vertices which are both in the positive and the negative support of ν , though they can only lie in one of those supports of μ . Suppose p_1 is in the positive support of μ but in both the positive and negative supports of ν . Thus, there is an edge (q, p_1) of $\Gamma(\nu)$ leading into it, and also an edge leading out of it. If the terminal vertex of the latter edge is in the negative support of μ , call it r ; if not, call it p_2 , and note that as a member of the positive support of μ and hence of ν , it also has an edge of $\Gamma(\nu)$ leading out of it, so we can repeat the process, looking at the terminal vertex of that edge. Since we have established that $\Gamma(\nu)$ has no cycles, this process must terminate, giving vertices q, p_1, \dots, p_k, r with edges directed from one to the next, where p_1, \dots, p_k are in the positive support of μ , but r is in the negative support.

Now let $\nu' = \nu_{q,r} - (\nu_{q,p_1} + \nu_{p_1,p_2} + \dots + \nu_{p_k,r})$. Like the element denoted by that symbol in the preceding argument, this satisfies $D(\nu') = 0$. Let us again form $\nu + \lambda \nu'$, this time choosing the value $\lambda > 0$ which leads to the cancellation of the smallest of the coefficients of the elements $\nu_{q,p_1}, \nu_{p_1,p_2}, \dots, \nu_{p_k,r}$ in ν . Since it does not reverse the sign of any of these coefficients, $\nu + \lambda \nu'$ still belongs to W_+ . Note that $\int_{(x,y) \in X \times X} d(x,y) d(\nu + \lambda \nu') \leq \int_{(x,y) \in X \times X} d(x,y) d\nu$, since by the triangle inequality, $d(q,r) \leq d(q,p_1) + \dots + d(p_k,r)$; so the property of minimizing the integral of $d(x,y)$ among elements of W_+ mapped to μ by D has not been lost. Also, $\Gamma(\nu + \lambda \nu')$ has dropped at least one edge that belonged to $\Gamma(\nu)$, since at least one coefficient was canceled, and has gained at most one edge, namely (q,r) (if that was not previously present); so the total number of edges has not increased. Finally, when we look at the sum of all the coefficients, we see that the coefficient of $\nu_{q,r}$ has increased by λ , while those of the $k+1$ elements $\nu_{q,p_1}, \dots, \nu_{p_k,r}$ have decreased by λ , so there has been a net change of $-k\lambda < 0$. Thus, we have a contradiction to our choice of ν as minimizing that sum. The same method works if some p_1 in the *negative* support of μ lies in both the positive and negative supports of ν . This completes the proof of the first assertion of our lemma.

The second is much easier. Suppose $\nu, \nu' \in W$, with $D(\nu) = D(\nu')$ and $\Gamma(\nu)$ and $\Gamma(\nu')$ both contained in Γ . Then $D(\nu - \nu') = 0$, and $\Gamma(\nu - \nu')$ is contained in Γ , hence has no cycles. Now if $\nu - \nu'$ is nonzero, its graph is nonempty, and having no cycles, it must have a leaf x . This means that when we evaluate $D(\nu - \nu')$, one and only one term contributes to the coefficient of μ_x , making that coefficient nonzero, and contradicting the assumption that $D(\nu - \nu') = 0$. Thus $\nu = \nu'$.

Finally, let us verify the parenthetical comment that the ν of the first assertion of our lemma need not be unique. Let X be a 4-point space $\{x_1, x_2, x_3, x_4\}$ where the distance between every pair of distinct points is 1, and let $\mu = \mu_{x_1} + \mu_{x_2} - \mu_{x_3} - \mu_{x_4}$. It is not hard to check that in this case the only elements ν that can possibly satisfy the conditions of the first assertion of our lemma are $\nu_{x_1, x_3} + \nu_{x_2, x_4}$ and $\nu_{x_1, x_4} + \nu_{x_2, x_3}$ (cf. (27)). Since these give the same value, $d(x_1, x_3) + d(x_2, x_4) = 2 = d(x_1, x_4) + d(x_2, x_3)$, the ν of the lemma cannot be unique.

(However, for most choices of metric on $\{x_1, x_2, x_3, x_4\}$, one of these two values is smaller than the other, and we do get a unique ν .) \square

Some rather disconnected remarks on the above –

The results from [20] that we called on at the beginning of the above proof, that the infimum of (29) is achieved, and by an element ν whose support is contained in that of μ , can in fact be obtained by a slight extension of the above arguments. One looks at any finite subset X_0 of X containing the support of μ , verifies by compactness that the infimum of (29) over elements ν with support in X_0 is achieved, then modifies the second part of the above proof slightly to apply not only to elements p_1 of the positive (respectively negative) support of μ that belong to both the positive and negative supports of our chosen ν , but also to elements $p_1 \in X_0$ *not* in the support of μ that belong to the positive and negative supports of ν , concluding again that no such elements exist. Letting X_0 then run over all finite subsets of X containing

the support of μ , one sees that the infimum of (29) reduces to the infimum with ν restricted to have support in the support of μ , as claimed.

Using Lemma 24, it is easy to verify that for the “sample questions” considered in our motivating remarks above, the right-hand sides of (27) and (28) are in fact the norms of the elements $\mu_{x_1} + \mu_{x_2} - \mu_{x_3} - \mu_{x_4}$ and $3\mu_{x_1} + \mu_{x_2} - 2\mu_{x_3} - 2\mu_{x_4}$ in U_0 , hence are, as we hoped, best possible bounds in those inequalities.

We can explain the “partial universality” result of Corollary 14(i) in terms of Lemma 24. Given any convex linear combination of points of our universal image of X , $\sum_I a_i \mu_{x_i}$ ($a_i > 0$, $\sum a_i = 1$), and any point $x \in X$ (which for simplicity we will assume is not one of the x_i , though the argument can be adjusted to the case where it is), the difference $\mu_x - \sum a_i \mu_{x_i}$ is an element of U_0 with positive support $\{x\}$ and negative support $\{x_i \mid i \in I\}$. For this situation, the conditions of Lemma 24 clearly lead to a unique $\Gamma(\nu)$, to wit, the tree whose edges are all pairs (x, x_i) ($i \in I$); and hence to the unique choice $\nu = \sum_i a_i \nu_{x, x_i}$. Thus, the right-hand side of (29) comes to $\sum_i a_i d(x, x_i)$, which is equal to the right-hand side of (19). In contrast, when one considers the difference between two general convex linear combinations of elements μ_x , as in Corollary 14(ii), there are generally many directed graphs satisfying the conditions of the above lemma, so the norm of that difference doesn’t have a simple expression.

Question 17 can be stated in terms of this universal construction. If, as in the discussion at the beginning of this section, we write $e : X \rightarrow U$ for the map $x \mapsto \mu_x$, and U_1 for the affine span of $e(X)$, and if we let $C \subseteq U_1$ be the convex hull of $e(X)$, then the terms $\text{map-rad}(X, \mathbf{NmV})$ and $\text{map-rad}(X, \mathbf{Conv})$ of (23) necessarily equal $\text{rad}_{U_1}(X)$ and $\text{rad}_C(X)$ respectively; so Question 17 is equivalent to asking whether the former radius can every be strictly less than the latter.

It follows from Lemma 24 that the norm of an element $\mu \in U_0$ can be evaluated by the following algorithm: Enumerate the spanning subtrees Γ of the bipartite graph having for vertex-sets the positive and the negative supports of μ , calculate for each such Γ the unique $\nu \in W$ with $D(\nu) = \mu$ and $\Gamma(\nu) \subseteq \Gamma$ (it is not hard to see that for Γ a spanning tree, such a ν exists), and evaluate the infimum of (29) over the subset of these ν that lie in W_+ . It would be interesting to know whether the number of computations required can be significantly reduced.

Weaver [20, p.43, next-to-last paragraph of §2.2] notes that for the analogous universal map of X into a normed *complex* vector space, it is no longer true that the infimum corresponding to (29) is always attained by a ν having the same support as μ . (Note: in the complex version of (29), we replace $d\nu$ by $|d\nu|$, instead of restricting ν to a “positive cone” as above. Weaver effectively does this for both the real and complex cases; the use of W_+ is one of the different technical choices that I mentioned I would make.) For instance, if $X = \{x, y_0, y_1, y_2\}$ with $d(x, y_i) = 1$ and $d(y_i, y_j) = 2$ ($i \neq j$), and if $\mu = \mu_{y_0} + \omega \mu_{y_1} + \omega^2 \mu_{y_2}$, where ω is a primitive cube root of unity, then the minimizing ν is $\nu_{y_0, x} + \omega \nu_{y_1, x} + \omega^2 \nu_{y_2, x}$, which makes that integral 3, while the best ν having support in the support of μ , $\{y_0, y_1, y_2\}$, seems to be $\frac{1}{3}(1 - \omega)\nu_{y_0, y_1} + \frac{1}{3}(\omega - \omega^2)\nu_{y_1, y_2} + \frac{1}{3}(\omega^2 - 1)\nu_{y_2, y_0}$, of which each term contributes $\frac{1}{3} \cdot \sqrt{3} \cdot 2$ to that integral, giving a total of $2\sqrt{3} = \sqrt{12} > 3$.

7 Appendix: Translating convex sets to 0.

We record here some observations related to the condition on a normed vector space V , that the radius relative to V of every convex subset C of V be equal to its radius relative to C itself. As noted earlier, this does not always hold; if it did, we could say that equality always held in (23), giving an immediate negative answer to Question 17. Rather, we shall see that it is likely that for $n > 2$, the only norms on \mathbb{R}^n with this property are those giving a structure isometric to \mathbb{E}^n . The observations below are not, so far as I can see, relevant to answering Question 17, but they seem of independent interest.

Lemma 25. *If V is a locally compact normed linear space, with closed unit ball B , then the following conditions are equivalent:*

(30) *For every nonempty convex subset C of V , one has $\text{rad}_V(C) = \text{rad}_C(C)$.*

(31) *Every nonempty closed convex subset C of B has a translate $C - v$ which contains 0 and is again contained in B .*

Proof. (31) \Rightarrow (30): Dilating by arbitrary constants, we see that if (31) holds for B , then it holds for rB for all positive real numbers r . Moreover, the statement that $C - v$ contains 0 and is contained in rB is equivalent to saying that $v \in C$ and that $v + rB$ contains C ; i.e., that C is contained in the ball of radius r about $v \in C$. Thus (31) says that if a closed convex set C is contained in some closed ball about some point of V (which may be taken without loss of generality to be 0), then it is contained in a ball of the same radius about one of its own points. This yields the case of (30) where C is closed. The facts that the convex hull of a finite subset of V is compact, hence closed, and that the radius of an arbitrary set is the supremum of the radii of its finite subsets, allow us to deduce the general case of (30) from the case of closed C .

(30) \Rightarrow (31): If C is a closed bounded convex subset of V contained in B , then $\text{rad}_V(C) \leq 1$, so by (30), $\text{rad}_C(C) \leq 1$. Moreover, compactness of C implies that the set of radii of closed balls containing C and centered at points $v \in C$ achieves this minimum $\text{rad}_C(C) \leq 1$, so that C is contained in a translate $v + B$ ($v \in C$); and this is equivalent to the conclusion of (31). \square

Now (31) is a statement purely about the convex set B in the topological vector space V , so it is natural to ask which subsets B of a topological vector space V satisfy it. Here are some pieces of language (one ad hoc, the rest more or less familiar), that we will use in examining this question.

Definition 26. If $C \subseteq B$ are convex subsets of a real vector space V , we shall call C parkable in B if there exists $v \in C$ such that $C - v \subseteq B$. When clear from context, “in B ” may be omitted.

If V is a real topological vector space, we will call sets of the form $\{x \in V \mid L(x) = a\}$, where L is a nonzero continuous linear functional on V and $a \in \mathbb{R}$, hyperplanes, while sets of the form $\{x \in V \mid L(x) \geq a\}$ will be called closed half-spaces.

A subset S of a vector space V will be called centrally symmetric if $S = -S$. A center of symmetry of a subset S of V will mean a point $v \in V$ such that $S - v$ is centrally symmetric; equivalently, such that $S = 2v - S$. (Note that a center of symmetry of a nonempty convex set belongs to that set.)

Lemma 27. Let B be a compact convex subset of \mathbb{R}^n containing 0. Then the following conditions are equivalent:

(32) The intersection of B with every hyperplane A that meets B is parkable.

(33) The intersection of B with every closed half-space H that meets B is parkable.

(34) Every nonempty closed convex subset C of B is parkable (= (31) above).

Proof. (34) \Rightarrow (32) is clear; we will show (32) \Rightarrow (33) \Rightarrow (34).

(32) \Rightarrow (33): Let H be a closed half-space in \mathbb{R}^n , bounded by a hyperplane A , and meeting B . If $H \cap B$ contains 0 it is trivially parkable, so assume the contrary. Thus B meets both H and its complement, hence it meets their common boundary A , so by (32) there exists $v \in A \cap B$ such that $(A \cap B) - v \subseteq B$. I claim that $(H \cap B) - v$ is also contained in B . Indeed, let $p \in H \cap B$; we wish to show $p - v \in B$. Intersecting our sets with the subspace of V spanned by p and v , and taking appropriate coordinates, we may assume that $n = 2$, that A is the line $\{(x, y) \mid y = 1\} \subseteq \mathbb{R}^2$, and that v is the point $(0, 1)$. H will be the closed half-plane $\{(x, y) \mid y \geq 1\}$, so we can write $p = (x_p, y_p)$ with $y_p \geq 1$.

In this situation, $A \cap B$ will be a line segment (possibly degenerate) extending from a point $(s, 1)$ to a point $(t, 1)$ ($s \leq t$). Since $(A \cap B) - v \subseteq B$, B also contains the segment from $(s, 0)$ to $(t, 0)$. Note that if $x_p > t$, then the point where the line segment from $p = (x_p, y_p) \in B$ to $(t, 0) \in B$ meets A would have x -coordinate $> t$, contradicting the assumption that $A \cap B$ terminates on the right at $(t, 1)$; so $x_p \leq t$. Similarly, $x_p \geq s$. Thus, $x_p \in [s, t]$, so $(x_p, 0) \in B$. Hence $p - v = (x_p, y_p - 1)$ lies on the line segment connecting $p = (x_p, y_p) \in B$ with $(x_p, 0) \in B$, hence lies in B , as claimed.

(33) \Rightarrow (34): Suppose C is a nonempty closed convex subset of B which is not parkable. By compactness of B , among the translates of C contained in B there is (at least) one that minimizes its distance to 0 in the Euclidean norm on \mathbb{R}^n ; let us assume C itself has this property. Let p be the point of C nearest to 0 and let A be the hyperplane passing through p and perpendicular (in the Euclidean norm) to p regarded as a vector. It is not hard to see that C will lie wholly in the half-space H bounded by A and not containing 0. Assuming (33), $H \cap B$ is parkable; say $v \in H \cap B$ with $(H \cap B) - v \subseteq B$. Since $v \in H$, if

we write v as the sum $ap + q$ of a scalar multiple of p and a vector q perpendicular to p , the coefficient a will be ≥ 1 , and so in particular, positive. It follows that for sufficiently small positive c , the point $p - cv$ will be closer to 0 than p is; moreover, if we take such a c that is ≤ 1 , $(H \cap B) - cv$ will still be contained in B , since $H \cap B$ and $(H \cap B) - v$ are. Hence $C - cv$ is contained in B , and has a point $p - cv$ which is closer to 0 than p is, contradicting our minimality assumption on C and p . \square

(In the above result, we could have replaced \mathbb{R}^n by any real Hilbert space; but \mathbb{R}^n seems more in keeping with the spirit of this note.)

Clearly, the closed Euclidean unit ball in \mathbb{R}^n satisfies (32), and hence (33) and (34); hence since those conditions are preserved by invertible linear transformations, so does the closed region enclosed by any ellipsoid centered at 0. On the other hand, our example in the paragraph containing (24) of a normed vector space in which (30) failed had for its unit ball B a 3-cube, showing that our properties fail for that B . To see geometrically the failure of (32) for B a cube, choose a vertex of the cube and pass a plane A through the three vertices adjacent thereto; it is not hard to see that $A \cap B$ is not parkable. One can similarly show that none of the regular polyhedra satisfies (32), nor does a circular cylinder, nor the solid obtained by attaching a hemisphere to the top and bottom of such a cylinder. In fact, for $n > 2$ I know of no compact convex subset of \mathbb{R}^n with nonempty interior that does satisfy that condition, other than the regions enclosed by ellipsoids centered at 0. The situation is different for $n = 2$, as shown by point (d) of the next result.

Lemma 28. *Suppose B is a centrally symmetric convex subset of \mathbb{R}^n . Then*

(a) *Any nonempty convex subset $C \subseteq B$ that has a center of symmetry is parkable in B .*

Hence, assuming in the remaining points that B is a compact centrally symmetric convex set, we have

(b) *If the intersection of B with every hyperplane A that meets B has a center of symmetry, then B satisfies the equivalent conditions (32)-(34).*

In particular,

(c) *If B is the closed region enclosed by an ellipsoid in \mathbb{R}^n , then B satisfies (32)-(34), and*

(d) *If $n = 2$, then without further restrictions, B satisfies (32)-(34).*

Proof. Let C be as in (a), with center of symmetry $z \in C$. Then for every $x \in C$, $2z - x \in C \subseteq B$, so by central symmetry of B , we have $c - 2z \in B$. Averaging c and $c - 2z$, we get $c - z \in B$. Thus $C - z \subseteq B$, so C is parkable.

It follows immediately that any B as in (b) satisfies (32), hence by Lemma 27, satisfies all of (32)-(34).

In the situation of (c), the intersection of B with a hyperplane A , if nonempty, is either a point or the region enclosed by an ellipsoid in A , hence has a center of symmetry, while in (d) the intersection of B with every line in \mathbb{R}^2 that meets B is a point or a closed line segment, hence has a center of symmetry; so in each case, (b) gives the asserted conclusion. \square

Question 29. *Let $n \geq 3$, and suppose B is a compact convex subset of \mathbb{R}^n having nonempty interior and containing 0. For the conditions listed below, is either or both of the implications (i) \Rightarrow (ii) \Rightarrow (iii) reversible?*

(i) *B is an ellipsoid centered at 0.*

(ii) *B is centrally symmetric, and for every hyperplane A meeting B , $A \cap B$ has a center of symmetry.*

(iii) *Every closed convex subset of B is parkable in B .*

Branko Grünbaum has pointed out to me a similarity between this question and the result of W. Blaschke [2, pp.157–159] that if E is a smooth compact convex surface in \mathbb{R}^3 with everywhere nonzero Gaussian curvature, such that when E is illuminated by parallel rays from any direction, the boundary curve of the bright side lies in a plane, then E is an ellipsoid. I believe that methods similar to Blaschke's may indeed show that both implications of Question 29 are reversible. To see why, suppose B is a compact convex subset of \mathbb{R}^3 with nonempty interior containing 0, which satisfies (iii) above, and whose boundary E is (as in Blaschke's result) a smooth surface with everywhere nonzero Gaussian curvature. Let A be any plane through 0, and A' the plane gotten by shifting A a small distance. Now the vectors that can possibly park $A' \cap B$ are constrained by the directions of the tangent planes to E at the points of $A' \cap E$ (which are well-defined because E is assumed smooth), and if we take A' sufficiently close to A , these tangent planes

become close to the corresponding tangent planes at the points of $A \cap E$. Applying the above observations to planes A' on both sides of A , one can deduce that all the tangent planes to E along $A \cap E$ must contain vectors in some common direction (I am grateful to Bjorn Poonen for this precise formulation of a rough idea I showed him); in other words, that $A \cap E$ is the boundary of the bright side when E is illuminated by parallel rays from that direction. By definition, $A \cap E$ lies in the plane A ; so we have the situation that Blaschke considered, except that we have started with planarity and concluded that the curve is a boundary of illumination, rather than vice versa.

That last difference is probably not too hard to overcome. More serious is the smoothness assumption on E , used in both the above discussion and Blaschke's argument. Finally, can the result be pushed from $n = 3$ to arbitrary $n \geq 3$? I leave it to those more skilled than I in the subject to see whether these ideas can in fact be turned into a proof that (iii) \Rightarrow (i) in Question 29.

A related argument which can be extracted from a key step in Blaschke's development shows that a compact convex subset B of \mathbb{R}^2 containing 0 and satisfying (34), whose boundary is a smooth curve containing no line segments, must be centrally symmetric. Again, one would hope to remove the conditions on the boundary.

One can ask about a converse to another of our observations:

Question 30. *Suppose C is a compact convex subset of \mathbb{R}^n ($n > 2$) such that every translate of C contained in a centrally symmetric compact convex subset B of \mathbb{R}^n is parkable in B . Must C have a center of symmetry?*

Here the behavior of a given C can change depending on whether the ambient vector space is 2-dimensional or, as in the above question, larger. For instance, a triangle C has the above property in \mathbb{R}^2 by Lemma 28(d), but not in \mathbb{R}^3 , as we saw in the example where B was a cube.

8 Acknowledgement.

I am indebted to W. Kahan for showing me the exercise he had given his Putnam-preparation class, of proving Lemma 2 in \mathbb{E}^3 , and for subsequently pointing out that my solution to that exercise worked in any normed vector space; and to Nik Weaver for information about his results in [20].
